

Carbon dioxide as a substitute for iodine contrast in arteriography during embolectomy

Uso de dióxido de carbono como substituto ao contraste iodado em arteriografia durante embolectomia

ABSTRACT

Acute limb ischemia can be potentially harmful to the limb and life threatening. Renal failure is a possible outcome associated with release of products of ischemic limb reperfusion. Some authors reported the benefit of performing angiography after embolectomy, even though iodine contrast is also nephrotoxic. We report a case of embolectomy on a patient with renal insufficiency in whom carbon dioxide was used as a substitute for iodine contrast.

RESUMO

A isquemia aguda de membro pode ser danosa para o membro e para a vida. A insuficiência renal é um desfecho possível associado à liberação dos produtos da reperfusão do membro isquêmico. Alguns autores relatam o benefício de realização de angiografia após embolectomia, apesar do contraste iodado também ser nefrotóxico. Relatamos um caso de embolectomia em uma paciente com insuficiência renal, em que o dióxido de carbono foi utilizado como substituto para o contraste iodado.

Descritores: Insuficiência renal crônica; Embolia; Angiografia; Dióxido de carbono; Traumatismo por reperfusão; Relatos de casos

INTRODUCTION

Acute embolic limb ischemia is an urgent clinical condition in which sudden decrease or worsening in limb perfusion causes a potential threat to extremity viability and to life.

Treatment consists of prompt revascularization with an embolectomy catheter. Thorough removal of all occlusive emboli in the arterial tree results in the best outcomes; hence, some authors favored arteriography after embolectomy for lower limbs.⁽¹⁾

Angiography is traditionally performed with iodinated contrast material, but carbon dioxide (CO₂) has been studied as an alternative intravascular contrast agent⁽²⁾ for patients with iodine allergy or renal function impairment. Since it is not nephrotoxic, it was considered reasonable to utilize this contrast in a patient with borderline renal function who would be submitted to the noxious stimuli of the reperfused limb after revascularization.⁽³⁾

To the best of our knowledge, this was the first case assessing the intraoperative use of CO₂ as a substitute for iodine contrast in a patient with known chronic kidney disease and an acute ischemic limb.

CASE REPORT

A 79-year-old woman presented to the emergency department with acute limb ischemia in her left leg with a 2-hour history. Past medical history was positive for hypertension, atrial fibrillation and non-dialysis-dependent chronic renal failure.

Two years before, she had been operated on for acute aortic embolic occlusion, with bilateral femoral catheter embolectomy. She started oral anticoagulation (warfarin) after this episode. Upon discharge she presented pedal pulses, but no posterior tibial pulses on either limb.

Medication use was irregular, and her international normalized ratio (INR) of prothrombin time upon admission was 1.1. Her pulse was arrhythmic; she was hypertensive (160x110mmHg) and presented with normal femoral, popliteal and pedal pulses on her right leg. On palpation in the left lower limb only a weak femoral pulse was observed; there were no distal pulses. The patient had pain and motor deficit. She was classified as grade IIb limb ischemia (immediately threatened) and was immediately referred for surgery.

Preoperative exams revealed a diminished creatinine clearance (Cockcroft-Gault of 12mL/min). General anesthesia was undertaken. Femoral access was performed on the scar tissue of the previous left femoral incision. Common, superficial and deep femoral arteries were dissected and clamped. Arteriotomy was performed and a 4-Fr embolectomy catheter was utilized (Edwards Lifesciences Corp, Irvine, California, USA). Thrombi were retrieved from both deep and superficial femoral arteries. The catheter progressed more than 60cm on the superficial artery, but could not be felt neither on pedal artery topography nor on posterior tibial artery topography. Back bleeding was not significant, and a decision was made to perform an angiography to better assess the infra-popliteal arterial tree. CO₂ was chosen as a substitute for iodine contrast for the angiography.

A homemade water seal CO₂ delivery system was used, similar to another previously described,⁽⁴⁾ but with one modification to prevent room-air contamination.⁽⁵⁾ Injection was performed through a KMP 4Fr catheter (Cook, Inc. Bloomington, Indianapolis, USA) inserted in the arteriotomy while the arteries were clamped.

Figure 1 shows a patent popliteal artery, a patent fibular artery and an occlusion on the mid-third of the anterior tibial artery. We hypothesized that the embolectomy catheter reached the fibular artery on the first attempt, and thus could not be felt on physical exam.

A new embolectomy was then performed. The catheter progressed to the foot, on the topography of the pedal artery (i.e., the catheter could be felt on the projection of the artery), and more thrombi were retrieved. Control angiography (Figure 2) showed complete resolution of the anterior tibial artery occlusion, with contrast up to the foot (Figure 3). A total of 28mL of CO₂ was used, and no iodine contrast was needed.

Arteriography was performed. The arteries were unclamped, and the popliteal and pedal pulses were noted to be present on the limb. Ischemia signs (e.g., pallor, hypothermia) were promptly resolved after arterial flow release. No compartment syndrome signs developed.

The patient remained in the intensive care unit (ICU) until the 11th postoperative day. During this

period, the patient did not receive any nephrotoxic agent, such as vancomycin or vasoactive drugs. She maintained diuresis stimulated by furosemide. After ICU discharge she developed a urinary tract infection, as well as deteriorating renal function and uremia. Dialysis was started on the 18th postoperative day. The patient developed pneumonia, which progressed to septic shock on the 36th day of her admission. She required vasoactive drugs for 2 days at the ICU and, unfortunately, her renal function was never fully recovered. She was discharged from hospital to a hospice care facility with a pedal pulse and no deficit on her limb, though requiring chronic dialysis.

DISCUSSION

Treatment of embolic arterial occlusion with severe limb ischemia is well defined and involves the use of an embolectomy catheter as the best alternative.⁽⁶⁾

CO₂ has been used electively in both diagnostic⁽⁷⁾ and therapeutic⁽⁸⁾ procedures in the femoropopliteal tree, and is reported to be safe⁽⁹⁾ and non-nephrotoxic.⁽¹⁰⁾

Intraoperative angiography was beneficial because it allowed the diagnosis of the arterial tree occlusion after the initial embolectomy. Additional removal of clots was performed and the result was documented as complete patency of the anterior tibial artery to the foot.

Our goal, when using CO₂, was to decrease the need for postoperative dialysis. Probably, in this case, the deleterious stimuli (surgical stress, urinary tract infection and septic shock due to pneumonia) contributed to renal failure and subsequent need for dialysis. The countermeasure (such as the use of non-nephrotoxic contrast) could have prevented renal failure if it were a single condition. If we had used the iodinated medium, we might wonder if something could have been done differently to avoid dialysis.

We consider CO₂ to be an alternative to iodine contrast when the decision to perform angiography is made in the acutely ischemic limb. To the best of our knowledge, this agent has never been described in this clinical setting; it presents good quality imaging, is not nephrotoxic and does not increase the risk for the limb or the patient in acute arterial occlusions. This approach may prove to be fruitful in patients with borderline renal function, thereby reducing the risk of short or long-term need for dialysis.
